

Hypothesis testing

Null & Alternative Hypothesis: The null hypothesis, H_0 is the commonly accepted fact; it is the opposite of the alternate hypothesis (H_1). Researchers work to reject, nullify or disprove the null hypothesis.

Why is it Called the “Null”?

The word “null” in this context means that it’s a commonly accepted fact that researchers work to nullify. It doesn’t mean that the statement is null itself! (Perhaps the term should be called the “**nullifiable hypothesis**” as that might cause less confusion).

Example: A researcher is studying the effects of radical exercise program on knee surgery patients. There is a good chance that the therapy will improve recovery time, but there's also the possibility it will make it worse. Average recovery times for knee surgery is 8.2 weeks.

H_0 (Null Hypothesis) : Average recovery times for knee surgery is 8.2 weeks.

H_1 (Alternative Hypothesis) : Average recovery times for knee surgery is NOT 8.2 weeks (could be more or less).

P-Value: When you perform a hypothesis test in statistics, a p-value helps you determine the significance of your results. The p-value is a number between 0 and 1 and interpreted in the following way: A small p-value (typically ≤ 0.05) indicates strong evidence against the null hypothesis, so you reject the null hypothesis.

A neurologist is testing the effect of a drug on response time by injecting 100 rats with a unit dose of the drug, subjecting each to neurological stimulus, and recording its response time. The neurologist knows that the mean response time for rats not injected with the drug is 1.2 seconds. The mean of the 100 drug injected rats' response time is 1.05 seconds with a sample standard deviation of 0.5 seconds. Do you think that the drug has an effect on response time?

H_0 : Drug has no effect on response time. (i.e., the mean response time is 1.2 seconds)

H_1 : Drug has an effect on response time. (i.e., the mean response time is not 1.2 seconds)

- * Assume H_0 is true \rightarrow From central limit theorem the mean of the sampling distribution is 1.2 seconds (population mean).

- * Now we have to find how likely(probability) that the response time is 1.05, when drug has no effect (null hypothesis)

- * That is how many standard deviations away 1.05 is from 1.2. This gives the area under the curve of a normal distribution.

- * Need to find standard deviation of the sampling distribution. The formula for this is = population SD/sqrt(# of samples)

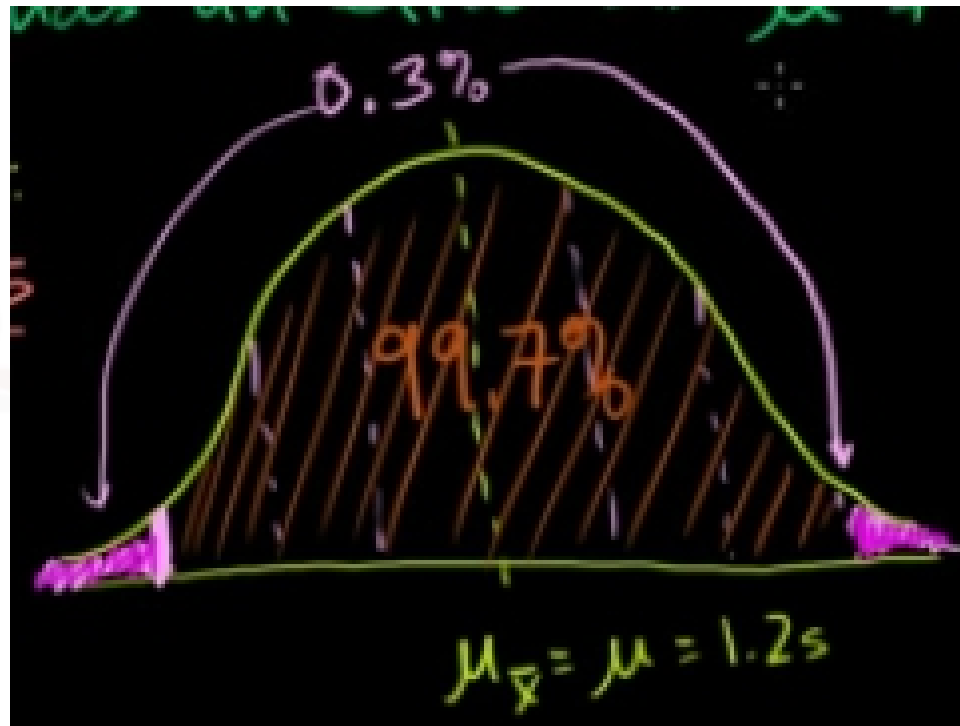

- * We don't know the population standard deviation, hence we take best approximation as 0.5 (sample SD) as population SD.

$$\begin{aligned}\text{Sampling distribution SD} &= 0.5/\text{sqrt}(100) \\ &= 0.5/10 \\ &= 0.05\end{aligned}$$

$$\begin{aligned}\text{Z-Score (how many SD away 1.05 from 1.2)} &= (1.2 - 1.05)/0.05 \\ &= 3\end{aligned}$$

* **P-value:** 3 standard deviations away (99.7%). Only 0.3% (P-value is 0.003) chance getting 1.05 seconds response when drug has no effect.

Hence H_0 (Null Hypothesis) is rejected.

One-tailed and Two-tailed Tests

The above example is a Two-tailed test. This depends on the alternative hypothesis we chose. Above example H_1 is looking for has an effect on response time, but not for more or less.

H_0 : Drug has no effect on response time (mean = 1.2 seconds)

H_1 : Drug has an effect on response time. (mean \neq 1.2 seconds)

One-Tailed test: If the H_1 is mentioned as below then it would have been One-Tailed test. The P-Value would have been 0.0015.

H_1 : Drug lowers the response time (< 1.2 seconds)

Z-Statistic vs T-Statistic

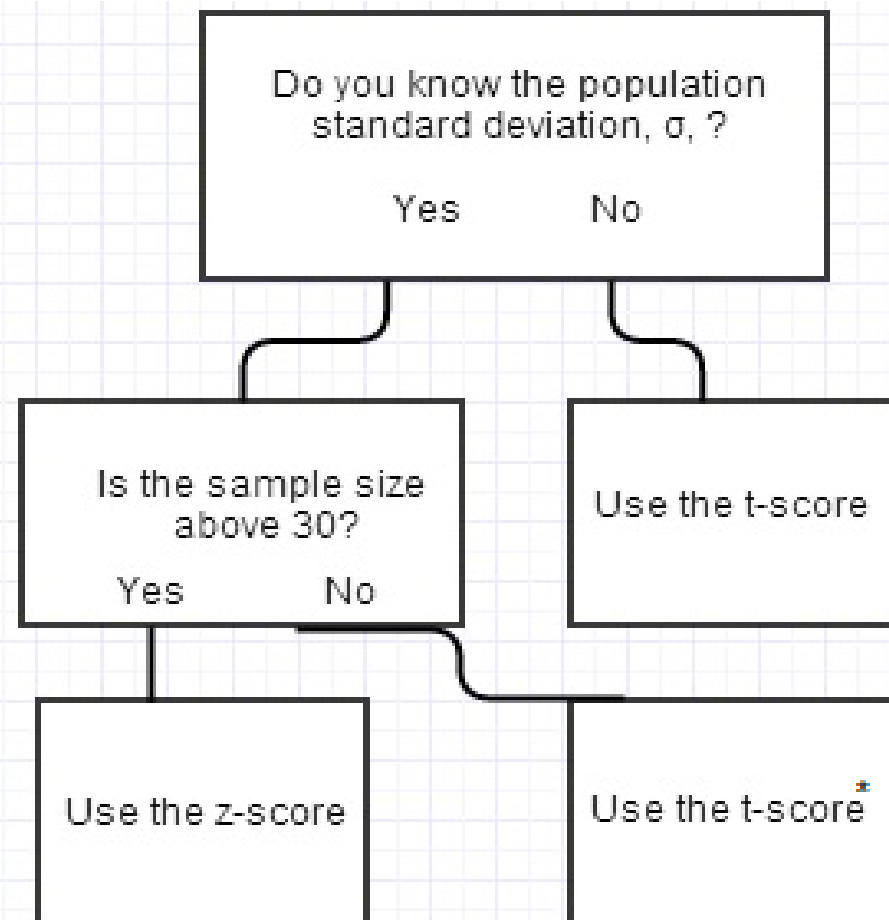

A z-score and a t score are both used in hypothesis testing. When sample size is less than 30 then use t-distribution, or else use z-distribution.

$$\sigma^2 = \frac{\sum (x - \mu)^2}{n}$$

$$z = (X - \mu) / \sigma$$

$$s^2 = \frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n - 1}$$

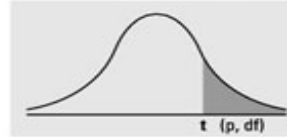

$$t = (X - \bar{X}) / s$$

* Replace s in the t-score formula with σ

T-Distribution Table

Numbers in each row of the table are values on a t -distribution with (df) degrees of freedom for selected right-tail (greater-than) probabilities (p).

| df/p | 0.40 | 0.25 | 0.10 | 0.05 | 0.025 | 0.01 | 0.005 | 0.0005 |

Chi-Square Goodness of Fit Test

When an analyst attempts to fit a statistical model to observed data, he or she may wonder how well the model actually reflects the data. How "close" are the observed values to those which would be expected under the fitted model? One statistical test that addresses this issue is the chi-square goodness of fit test.

In general, the chi-square test statistic is of the form

$$\chi^2 = \sum \frac{(\text{observed} - \text{expected})^2}{\text{expected}}$$

Example: A new casino game involves rolling 3 dice. The winnings are directly proportional to the total number of sixes rolled. Suppose a gambler plays the game 100 times, with the following observed counts:

| Number of Sixes | Number of Rolls |
|-----------------|-----------------|
| 0 | 48 |
| 1 | 35 |
| 2 | 15 |
| 3 | 3 |

The casino becomes suspicious of the gambler and wishes to determine whether the dice are fair. What do they conclude?

* Probability to rolling a 6 on any given toss – $1/6$. Assuming the 3 dice are independent (the roll of one die should not affect the roll of the others), we might assume that the number of sixes in three rolls is distributed Binomial.

* To determine whether the gambler's dice are fair, we may compare his results with the results expected under this distribution. On 3 dies

$$P_p(n | N) = \binom{N}{n} p^n q^{N-n}$$

$$= \frac{N!}{n! (N-n)!} p^n (1-p)^{N-n},$$

Null Hypothesis:

- The expected values for 0 sixes $P(X=0) = 3C_0 \times (1/6)^0 \times (1-1/6)^3 = 1 \times 1 \times (5/6)^3 = 0.578$
- The expected values for 1 sixes $P(X=1) = 3C_1 \times (1/6)^1 \times (1-1/6)^2 = 3 \times (1/6) \times (5/6)^2 = 0.347$
- The expected values for 2 sixes $P(X=2) = 3C_2 \times (1/6)^2 \times (1-1/6)^1 = 3 \times (1/6)^2 \times (5/6)^1 = 0.069$
- The expected values for 3 sixes $P(X=3) = 3C_3 \times (1/6)^3 \times (1-1/6)^0 = 1 \times (1/6)^3 \times 1 = 0.005$

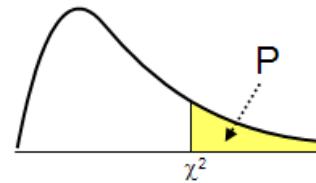

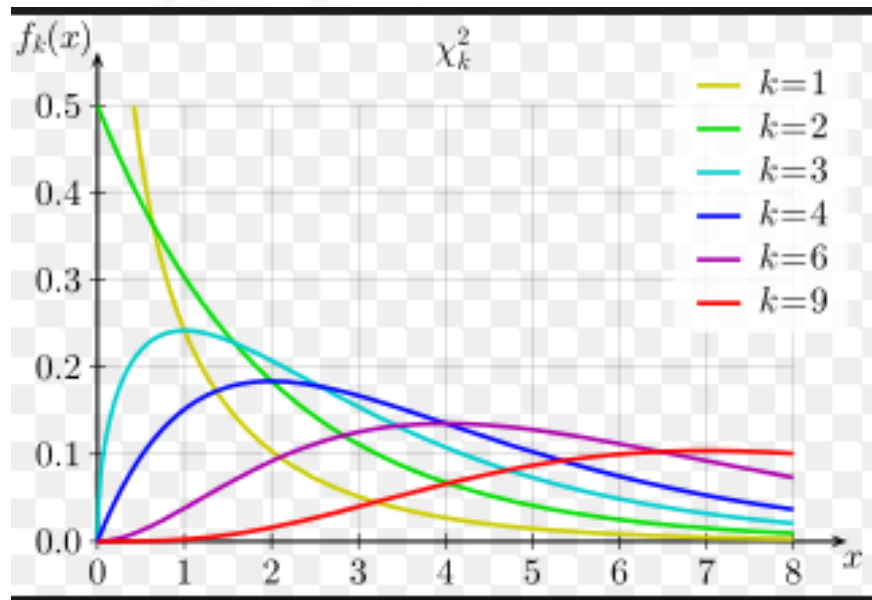

Since the gambler plays 100 times, the expected counts are the following:

| Number of Sixes | Expected Counts | Observed Counts |
|-----------------|-----------------|-----------------|
| 0 | 58.0 | 48 |
| 1 | 34.5 | 35 |
| 2 | 7.0 | 15 |
| 3 | 0.5 | 3 |

The chi-square statistic is $= (48-58)^2/58 + (35-34.5)^2/58 + (15-7)^2/7 + (3-0.5)^2/0.5$
 $= 1.72 + 0.007 + 9.14 + 12.5$
 $= 23.367.$

* We need to look into Chi-Square distribution table and curve. We have four random variables, hence the degrees of freedom is 3.

* If we are interested in a significance level of 0.05 we may reject the **null hypothesis (that the dice are fair)** if > 7.815 , the value corresponding to the 0.05 significance level (,3 df) for the distribution. Since 23.367 is clearly greater than 7.815, we may reject the null hypothesis that **“the dice are fair at the 0.05 significance level”**.

| | P | | | | | | | | | | |
|----|-----------|----------|--------|--------|--------|--------|--------|--------|--------|--------|--------|
| DF | 0.995 | 0.975 | 0.20 | 0.10 | 0.05 | 0.025 | 0.02 | 0.01 | 0.005 | 0.002 | 0.001 |

F- Statistic (ANOVA)

Figure out how much of the total variance comes from:

The variance *between* the groups

The variance *within* the groups

Calculate the ratio:

$$F = \frac{\text{between groups}}{\text{within groups}}$$

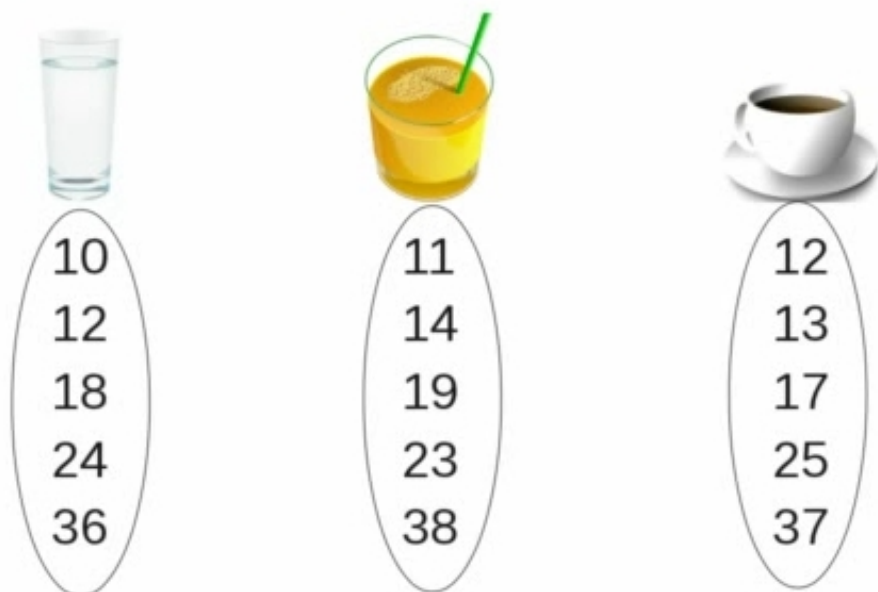

The larger the ratio, the more likely it is that the groups have different means (reject H_0).

Suppose that three groups have given water, fruit juice, coffee. Now we want to test the response between three groups. We have to use F-test as we have more than two groups (otherwise we would have used t-test)

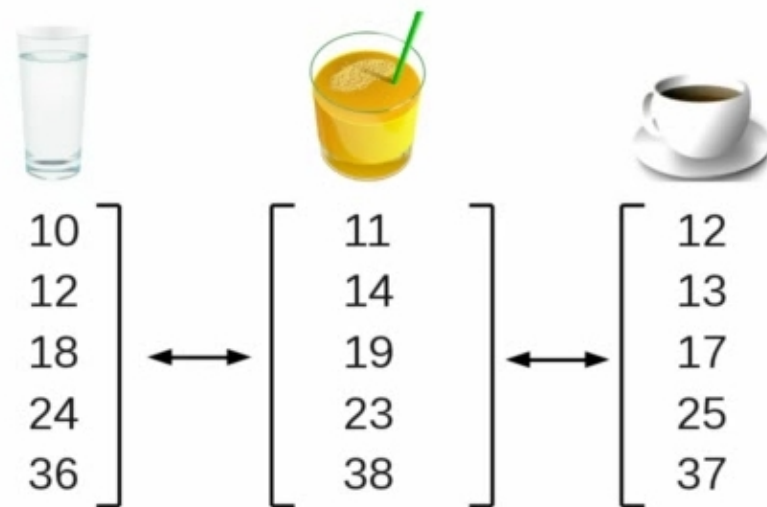

Null Hypothesis: Drink didn't make much difference

Example 1: Lot of variation with in group, but a little between groups.

This case we will **accept** Null Hypothesis, variation between groups is not much.

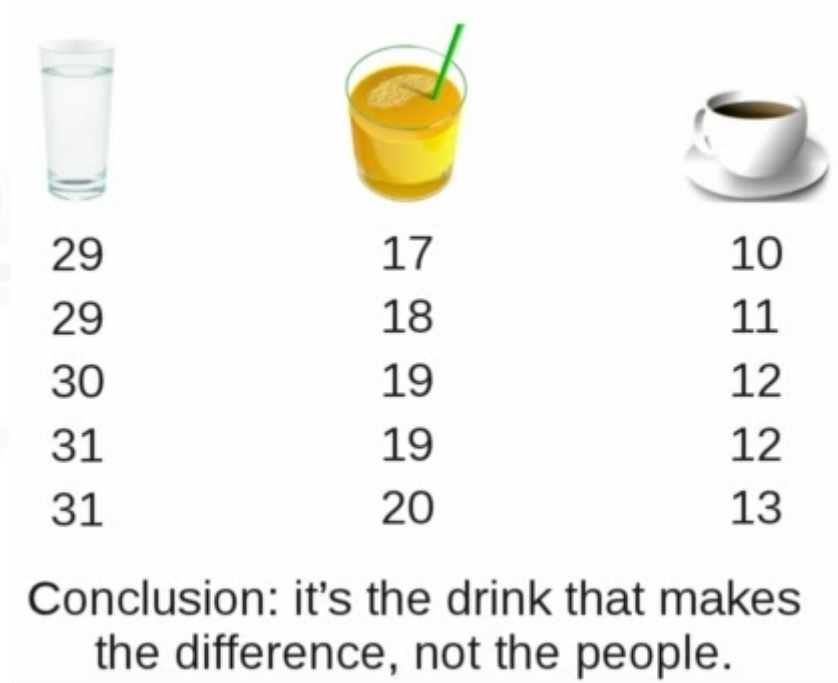

There's a lot of variation in each group...

...but each group looks pretty much the same.

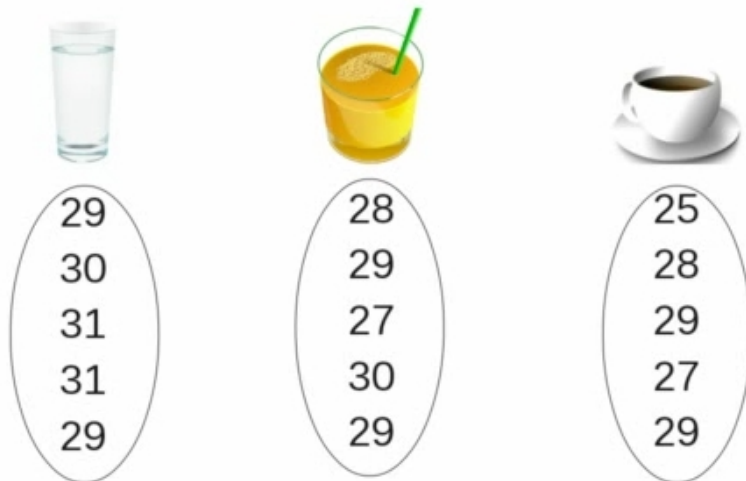

Example 2: A little variation within group, but a lot of variation between groups.

This case we will **reject** the Null Hypothesis

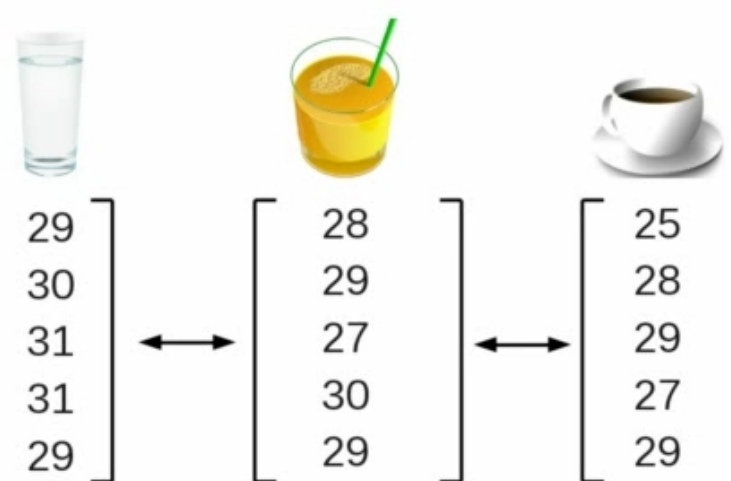

Example 3: There is not much variation with in OR between groups.

The result of ANOVA calculation is $F(2, 12) = 4.7$, the p-value = 0.04 (from F-distribution table). We can **reject** the Null Hypothesis.

Variation within each group

Variation between the groups

Calculate the degrees of freedom as follows:

$$F(\textcolor{red}{b}, \textcolor{blue}{w})$$

b is the degrees of freedom for variance between groups.

w is the degrees of freedom for variance within groups.

b = number of groups – 1

**w = total number of observations –
number of groups**

ANOVA Calculation example

Sample 1 : Stress under normal condition

Sample 2 : Stress after announced layoffs

Sample 3 : Stress during layoffs

Need to measure the impact of announced layoffs.

Null Hypothesis : No impact of announced layoffs on employee stress

Skewness

Consider the two distributions in the figure just below. Within each graph, the values on the right side of the distribution taper differently from the values on the left side. These tapering sides are called tails, and they provide a visual means to determine which of the two kinds of skewness a distribution has:

negative skew: The left tail is longer; the mass of the distribution is concentrated on the right of the figure. The distribution is said to be left-skewed, left-tailed, or skewed to the left, despite the fact that the curve itself appears to be skewed or leaning to the right; left instead refers to the left tail being drawn out and, often, the mean being skewed to the left of a typical center of the data. A left-skewed distribution usually appears as a right-leaning curve.

positive skew: The right tail is longer; the mass of the distribution is concentrated on the left of the figure. The distribution is said to be right-skewed, right-tailed, or skewed to the right, despite the fact that the curve itself appears to be skewed or leaning to the left; right instead refers to the right tail being drawn out and, often, the mean being skewed to the right of a typical center of the data. A right-skewed distribution usually appears as a left-leaning curve.[1]

Skewness in a data series may sometimes be observed not only graphically but by simple inspection of the values. For instance, consider the numeric sequence (49, 50, 51), whose values are evenly distributed around a central value of 50. We can transform this sequence into a negatively skewed distribution by adding a value far below the mean, e.g. (40, 49, 50, 51). Similarly, we can make the sequence positively skewed by adding a value far above the mean, e.g. (49, 50, 51, 60).

The Pearson mode skewness, or first skewness coefficient, is defined as

$$\frac{\text{mean} - \text{mode}}{\text{standard deviation}}$$

The Pearson median skewness, or second skewness coefficient, is defined as

$$\frac{3 (\text{mean} - \text{median})}{\text{standard deviation}}$$

Person MODE vs MEDIAN skewness: Pearson's first coefficient of skewness uses the mode. Therefore, if the mode is made up of too few pieces of data it won't be a stable measure of central tendency. For example, the mode in both these sets of data is 9:

1 2 3 4 5 6 7 8 9 9.

1 2 3 4 5 6 7 8 9 9 9 9 9 9 9 9 9 9 9 10 12 12 13.

In the first set of data, the mode only appears twice. This isn't a good measure of central tendency so you would be cautioned not to use Pearson's coefficient of skewness. The second set of data has a more stable set (the mode appears 12 times). Therefore, Pearson's coefficient of skewness will likely give you a reasonable result.

Interpretation (Skewness):

- The direction of skewness is given by the sign.
- The coefficient compares the sample distribution with a normal distribution. The larger the value, the larger the distribution differs from a normal distribution.
- A value of zero means no skewness at all.
- A large negative value means the distribution is negatively skewed.
- A large positive value means the distribution is positively skewed.

Kurtosis

Population Kurtosis Formula

$$K = n \frac{\sum_{i=1}^n (X_i - X_{avg})^4}{(\sum_{i=1}^n (X_i - X_{avg})^2)^2}$$

Sample Kurtosis Formula

$$K = \frac{n(n+1)(n-1)}{(n-2)(n-3)} \frac{\sum_{i=1}^n (X_i - X_{avg})^4}{(\sum_{i=1}^n (X_i - X_{avg})^2)^2}$$
